Out of Africa

The Ebola outbreak in West Africa must be shut down now, or the disease will continue to spread.

Ebola is out of control in Liberia, Sierra Leone and Guinea. Although this has been the case since late spring, the international pledges of help have yet to translate into concerted, rapid action on the ground. The virus still has the upper hand. Between 23 September and 1 October alone, the number of cases rose from 6,500 to almost 7,500, according to the World Health Organization.

The situation has become so bad that no one knows the true numbers of cases and deaths, only that they are probably much larger than official estimates. And the accompanying collapse of the countries' health systems means that people are unnecessarily falling victim to malaria and other diseases. One does not need a mathematical model to foresee how bad this could get.

The biggest risk is that the outbreak will spread to neighbouring countries. The risk to the rest of the world, and in particular to richer countries, remains low. But there is no room for complacency. Spain and the United States have now had cases, and the hapless management of the US case serves as a reminder that even a country with probably the most developed plans for responding to biological threats — be they natural or terrorist — can fall far short when put to the test. The infected man had flown from Liberia to Dallas, Texas, on 20 September. Four days later, he started to develop symptoms; he went to the hospital on 26 September, but no red flags were raised and he was sent home. He was not isolated until 28 September, after returning to the hospital in an ambulance.

The people he had been staying with were then quarantined, but spent more than a week in an apartment that still contained his Ebola-contaminated clothing and linen, which they had to decontaminate and bag as best they could. Meanwhile, local, state and federal officials argued over their disparate laws governing the decontamination and transport of dangerous pathogens, before belatedly sending in a commercial clean-up team.

The US health system is sufficiently robust to stop a full-blown outbreak developing. But even in rich countries, inequalities in access to health care and cost-cutting in the health services can create vulnerabilities. Strong public-health systems, with sufficient slack in them to provide the surge capacity that is needed in a serious outbreak, are a crucial defence.

The average life expectancy in the United States lags behind that of many other developed nations. Although its richest areas boast some of the highest expectancies in the world, some places have expectancies even lower than those in developing countries such as Bangladesh. Were Ebola to spread in underprivileged urban areas, it might not be so easy to control as US officials are making out. The uninsured, in particular, may think twice about going to see a doctor, and so hamper efforts to stem an outbreak.

The media's handling of the first US-diagnosed case also carries lessons. Although much of it has been first-class, the dogged determination to identify the infected man and who he came into contact with could be counterproductive. People who suspect they might have been

in contact with someone infected with Ebola might now be reluctant to come forward in case their names are splashed all over the headlines. The public has a legitimate interest in knowing the places an infected person has frequented, for example, but there is a fine line between this and blatant voyeurism, invasion of privacy and sensationalism.

More broadly, the excessive media and political focus on the threat to the United States and other Western countries — which is relatively low — risks engendering a siege mentality. And as Thomas Frieden, director of the US Centres for Disease Control and Prevention, has pointed out, flight bans and other restrictive measures only hamper access by relief agencies, and diminish the much-needed cooperation of local communities. The first US-diagnosed case, he says, is a stark reminder that the threat of exported cases will persist until the outbreak is quashed.

The world is fiddling while West Africa burns, and unless it acts much faster, the outbreak risks spreading to surrounding regions. Sparks from it could lead to exports to more far-flung places, perhaps even to major cities that lack decent public-health infrastructure. But countries and the public must also realize that although action is needed urgently, the commitments must be sustained until the outbreak has been stamped out, which could take many months. The relatively low threat to developed countries must not distract or detract from the pressing need to tackle the outbreak at its source. ■

“The world is fiddling while West Africa burns.”

A little knowledge

The significance of expertise passed on by direct contact — tacit knowledge — is moot.

For the last two decades of the twentieth century, a cold war rumbled on between the laboratories of physicists in Moscow and in the West over the quality of sapphire. The Russian scientists claimed to have measured the rate of decay of the material's resonance — a signal of its quality — with what researchers elsewhere considered impossible precision. The stakes were high: sapphire mirrors were being considered for use in a new generation of laser interferometer gravitational-wave detectors. But were they up to the task? Labs in the United States and United Kingdom could not reproduce the Moscow findings. The discrepancy fuelled mistrust and antagonism.

At the turn of the millennium, the mystery was solved. Measuring the quality of sapphire, it turns out, is as much art as science. The Moscow scientists were expert experimenters, but this expertise was not transferred through the methods sections of their academic papers. The fine fibres used to suspend the sapphire cylinders under investigation

were greased with “the presence of a fatty film”, one of their translated papers pointed out. Less explicit was the source of the grease. Only after years of struggling with various lubricants did the Western researchers realize that one member of the Russian group would sometimes run the thread across the bridge of his nose or behind his ear. With the right amount of human ‘flossing’ (and the right human), the Western scientists managed to get similar results.

The thread greasing is an example of tacit knowledge: know-how that can be passed on only through direct contact, and not by written or verbal instruction. How to ride a bicycle is a classic case. How to make an atomic bomb is a less-well-known example: all the instructions to build a nuclear weapon may be there on the Internet, but the ‘been there, done that’ personal experience is not. Indeed, security analysts have suggested that the lack of active testing and consequent erosion of nuclear-weapon tacit knowledge is leading to the “uninvention” of the bomb, and reduced credibility of the nuclear deterrent.

In a paper published this month in the journal *Science and Public Policy*, researchers in the United Kingdom suggest that a reverse process is under way when it comes to biology and biological weapons (J. Reville and C. Jefferson *Sci. Public Policy* 41, 597–610; 2014). Access to tacit knowledge in the life sciences is not dwindling but proliferating, argue James Reville and Catherine Jefferson. As secrets are shared, chiefly through advances in information and communications technology, tacit knowledge becomes explicit and barriers are demolished. And it is worth considering, they point out, what those barriers have held back. Many attempts have been made to manufacture deadly ricin, for example, probably based on Internet recipes, but most fail to truly weaponize the material by not milling it to the necessary particle size.

“Even where optimised weaponisation is not the strategic goal,” the authors write, “tacit knowledge may be an important limiting factor in the ability of unskilled actors to exploit advances in [science and technology], which has important implications for the way in which threat is assessed.” Policy-makers who try to proscribe the

development of biological weapons should first gain a better idea of what is scientifically possible and what is not, they suggest, and a sense of how that is changing.

What has any of this to do with the work of a regular bench scientist? Quite a lot, actually. As more attention is paid to the ‘reproducibility crisis’ in science, and journals and funders wrestle with how to make published research findings more robust, tacit knowledge has emerged as both a problem and an opportunity.

In a Comment piece in this journal last year (M. Bissell *Nature* 503, 333–334; 2013), Mina Bissell warned that the push to replicate findings could unfairly malign research (and researchers) that — just like measuring sapphire quality — relies on tacit-knowledge techniques that are better learnt than studied. The *Journal of Visualized Experiments* already aims to narrow the gap between tacit and explicit knowledge by requiring scientists to video their techniques, and so show colleagues how to conduct procedures, rather than simply telling them.

There are known unknowns and unknown unknowns, as former US defence secretary Donald Rumsfeld clumsily explained. Some tacit knowledge is deliberately withheld, and some journal methods sections offer insufficient space for elaboration. Those are the known unknowns and are most easily addressed. The tacit knowledge that is harder to pass on is the nugget of information that neither the teacher nor the pupil realized was important: the varnish on the Stradivarius violin; the greasing of the thread behind the ear.

The trend in science is towards greater openness and data sharing. Communication is instant and in real time; knowledge has never been more fluid. Science traditionally argues that this is a good thing. There is no inherently good or bad technology, goes the mantra, only good and bad applications. Is the same true for all forms of knowledge? One way or another, we could be poised to find out. ■

“Knowledge has never been more fluid — a good thing, science traditionally argues.”

Holy cows

A mass beaching of walrus in Alaska is a sign of things to come.

For more than a century the central attraction of the Horniman Museum in London has been a too-large stuffed walrus. Victorian taxidermists, the story goes, had never seen a live walrus, so they simply kept filling the floppy hide until the creature seemed to fit its skin. The bloated specimen spends its days looking down on visitors with an erect and noble posture that it never held in life.

Compared to the photogenic polar bear, the walrus, even one as smoothed for the camera as the Horniman’s, makes an unlikely poster species for climate change. But cram the creatures together — 35,000 of them — on a remote Arctic beach, and impose a no-fly zone above to prevent the carnage of a stampede, and it is tempting to see them as the natural world’s latest distress beacon to warn of the creeping chaos of global warming.

In the last week, environmental campaigners have cried that the mass walrus beaching in Alaska, first spotted last month, is another clear signal of our warming world. Climate-change sceptics insist that the event is nothing unusual, and have dug out records of previous mass walrus ‘haul-outs’ to support their case. Delighted by the novelty (images of melting glaciers are so 2009), much of the media has discussed the story, and tried hard to work in a Beatles song reference.

There is a simple way to tell this tale. Walrus spend much of their time out of the water, especially when they are rearing young. They prefer to perch on floating sea ice, which gives them access to the

seabed, where most of their food lives. As sea ice retreats north — and this year provided the sixth-lowest extent of summer Arctic ice on record — more walrus have to haul themselves onto the coast. Since 2000, increasing numbers of Pacific walrus (the Atlantic population is less affected) have been forced onto the beaches around the Chukchi Sea; in October 2010, scientists counted a gathering of 120,000 at Cape Serdtse-Kamen in Russia.

Walrus haul-outs on the coast tend to be dominated by adult males. The current event features substantial numbers of mothers and young, which makes it more worrying. A walrus stampede might sound unlikely, but it is a genuine risk. Spooked animals rush to the water and trample anything in their path. The demographics also suggest that something out of the ordinary is going on: female walrus usually recognize the risks of mass haul-outs, and leave the bulls to it.

The link between increased walrus haul-outs on Arctic beaches and the decreased availability of sea ice is clear-cut. The link to climate change is less so, at least in the short term. Sea-ice cover fluctuates with wind and currents from year to year, and the key for walrus is the position of the ice as much as its extent. They need ice over the continental shelf so that they can both rest and feed. In 2008, when remnant ice remained in the Chukchi Sea in the shallow waters of the shelf, walrus did not come ashore in significant numbers.

Whether or not this particular haul-out of walrus in Alaska is a result of climate change is ultimately a moot point. Annual peaks and troughs — of animal movement and ice measurements — are symbolic, but the long-term trend is clear: the Arctic is warming, its ice is melting and the walrus’s traditional habitat is disappearing. The walrus of the Pacific Arctic face an uncertain future. They might be able to move, they might be able to adapt. Or they might be stuffed. ■
